PURPOSE
In this study, we aimed to investigate the breast lesion excision system (BLES) as a tool and a practical alternative technique to surgical biopsy and other percutaneous biopsy methods for suspicious lesions. We also wanted to share our initial experience with BLES and compare it with standard percutaneous biopsy methods.

METHODS
From July 2015 to December 2016, a total of 50 patients who had high-risk lesions which were diagnosed with core needle biopsy (CNB) or had lesions with radiology pathology discordance, or had high-risk factors, high-grade anxiety, or suspicious follow-up lesions were enrolled in the study. These lesions were classified as Breast Imaging Reporting and Data System (BI-RADS) 3 or 4, which are under 2 cm. Pathologic diagnoses before and after BLES were evaluated comparatively. The diagnostic and therapeutic success and the complications of CNB and BLES were analyzed.

RESULTS
After BLES, two cases were diagnosed as atypical lobular hyperplasia and atypical ductal hyperplasia. Since the surgical margin was negative, re-excision was not required. Two cases were diagnosed as malignant, and no residual tissue was detected in the operation region. Total excision rates were reported as 56%. Minor hematoma was observed in only 1 out of 50 cases (2%), and spontaneous remission was observed. Two patients (4%) complained of pain during the procedure. Radiofrequency-related thermal damage to the specimen showed: Grade 0 (<0.5 mm) damage in 88%, Grade 1 (0.5–1.5 mm) in 10%, Grade 2 (>1.5 mm or thermal damage in diffuse areas) in 2%, and Grade 3 (diffuse thermal damage or inability to diagnose) in 0%. We found a significant positive correlation between classification of thermal damage and lesion fat cell content ($r = 0.345$, $P = 0.015$).

CONCLUSION
BLES is a safe technique that can be effectively used with low complication rates in the excision of benign and high-risk breast lesions in selected cases. It may also provide high diagnostic success and even serve as a therapeutic method in high-risk lesions, such as radial scar, papilloma, and atypical lobular hyperplasia with high complete excision rates without fragmentation of lesions.

With the increased effectiveness of screening programs, the incidence of non-palpable breast lesions is also increasing. This situation leads to an increase in the rate of diagnostic biopsies for suspicious lesions (1–3). All preferred percutaneous biopsy methods have both advantages and disadvantages. The ideal biopsy method should obtain pathologic specimens in larger sizes to increase diagnostic accuracy and minimize the necessity of recurrent biopsy in suspicious results. It should prevent the loss of time and energy and allow the evaluation of surgical margins in possible malignant lesions. The lesion should be examined by the appropriate imaging methods and the most effective biopsy method should be chosen. The selected biopsy method should be minimally invasive, yet be able to give the most definitive result, while not affecting the next possible surgical procedure. The goal is to avoid unnecessary surgical procedures for benign lesions, while avoiding recurrent biopsies by obtaining sufficient tissue from high-risk and malignant lesions to plan a treatment course.

Although surgical excision is the gold standard for suspicious lesions, the use of minimally invasive breast biopsy methods in the preoperative evaluation of nonpalpable suspected breast lesions is increasingly recommended (4, 5). Percutaneous biopsy has provided a simple, relatively inexpensive, and cosmetically acceptable alternative to open surgical biopsy for the assessment of suspicious breast lesions (6). These procedures can be performed under the guidance of ultrasonography (US), as well as stereotactic X-ray or magnetic resonance imaging (MRI). These methods include core needle biopsies (CNBs), vacuum-assisted core needle biopsies (VACNBs), and, finally, the use of the breast lesion excision system (BLES). BLES is a method that can be applied under local anesthesia in outpatient conditions. With a single entry, the target lesion is surrounded by the hooks from the probe tip. By using radiofrequency (RF) energy, the lesion is separated from the tissue, and the target tissue is removed from the breast tissue through the entrance route. With this method, a large unfragmented biopsy specimen can be obtained in one piece.

The underestimation rates of atypical ductal hyperplasia (ADH) and ductal carcinoma in situ (DCIS) are used to determine the accuracy of percutaneous breast biopsy techniques (7). The literature shows low underestimation rates in high-risk lesions, such as DCIS and ADH in VACNB, when compared with CNB (8, 9). In addition to conventional needle aspiration biopsies and CNBs, Liberman et al. (10) have shown that VACNBs can be used as a starting point in the diagnosis of mammographic microcalcifications.

Main points

- BLES is a biopsy technique that uses radiofrequency energy to enter a small incision made in the skin under local anesthesia and remove the suspected lesion in a single-piece percutaneously.
- Breast lesion excision system (BLES) is a safe and valid method with more accurate diagnosis of suspected breast lesions with mismatched radiology-pathology findings compared with other percutaneous biopsy methods.
- Short hospital stays, outpatient setting, minimal incision, and good cosmetic results are the advantages of BLES over surgical biopsies.
- Complete resection with safe surgical margins can be easily achieved in cases where the target lesion is smaller than 10 mm.

BLES is a safe method that has been used as an alternative to VACNB since 2001 (11–13). The procedure can be done under both mammography and US guidance. Also, the BLES technique can be used for excisional removal of benign or high-risk lesions as an alternative to conventional surgical excision in appropriate cases (1). In preliminary studies on the BLES technique, DCIS underestimation rates were 3%–21% (1, 12, 13) and recent studies reported the total excision rates in malignant and suspicious lesions as 30%–76.3% (13–24).

In this study, we aimed to investigate whether the BLES technique is a therapeutic method that can be a useful and practical alternative to surgical biopsy and other percutaneous biopsy methods in benign and high-risk lesions. We compared our initial experience with BLES to standard percutaneous biopsy methods.

Methods

From July 2015 to December 2016, a total of 50 cases who applied to the breast clinic were included in this study. Each patient provided written informed consent prior to the procedure, and approval was obtained from the local ethics committee for the study.

All patients were examined by a general surgeon and a radiologist. Mammographic evaluation was performed for all patients over 40 years of age, and a detailed evaluation was made by US in all cases. All lesions were classified using the Breast Imaging Reporting and Data System (BI-RADS). Before the BLES procedure, 49 patients underwent CNB. One patient, with suspicious microcalcifications in mammography classified as high risk, underwent the BLES procedure without previous CNB.

The indications for the procedure included BI-RADS 3 and 4 lesions <20 mm meeting the following criteria:

a) Lesions that have radiology pathology discordance, (nonspecific benign diagnosis in the pathology reports of lesions with BI-RADS 4 in the presence of real mass, undefined calcification in the pathology report, calcifications that are defined in the radiology report while there is no calcification in the mammography exam);

b) Lesions (ADH, lobular neoplasm, radial scar, papillary lesions, columnar cell changes) defined as high-risk lesions in the pathology report;

c) Patients who have high-risk factors (family history of breast cancer, breast drainage therapy), or those who did not want to be followed up due to high anxiety.

Patients with a body weight of more than 120 kg, patients with chronic respiratory problems, patients with severe heart failure, patients with pace-makers, and patients who were pregnant were excluded from the study.

Pre-procedural bleeding time, prothrombin time, partial prothromplastin time, and internationalized normalized ratio (INR) were measured. Aspirin was discontinued five days prior to the procedure, and patients receiving coumadin medications were switched to low molecular weight heparin.

The same surgical-radiology team performed 49 procedures under US guidance (Fig. 1) and one lesion under stereotactic mammography guidance. According to the localization and size of the lesion, the appropriate basket size was selected (15 mm or 20 mm) in order to provide complete excision of the lesion as much as possible. A cautery plate was placed on the back of the patient before the procedure. With the imaging guidance, 20 mL of 1% lidocaine combined with 1:100.0000 epinephrine was applied to the quadrant of the targeted lesion. To remove lesions close to the skin or pectoral muscle,

Figure 4. After the BLES biopsy, a suture is visible on the skin.

the distance between the tissues was increased by applying local anesthesia to the area between the lesion and the skin or between the lesion and the pectoral muscle. A cut of about 6–8 mm was made on the skin.

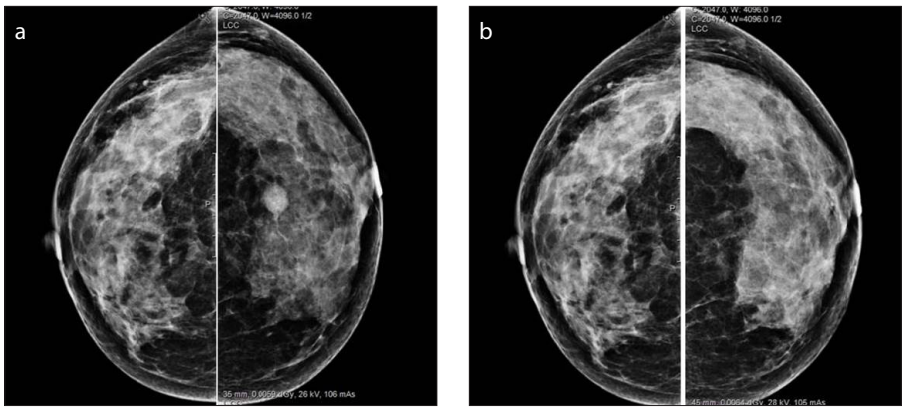

Figure 5. a, b. Mammography image **(a)** shows an indeterminate lesion in the left breast. Image **(b)** taken one year after the BLES biopsy, in the routine follow-up of the area of the lesion, shows no residue.

In the imaging guidance, the wand was positioned to border the target lesion. After the RF was run, the lesion was surrounded by five metallic prongs emerging from the tip of the wand for 10 s, and the lesion was separated from the adjacent tissue by burning. Gases and liquids produced due to tissue heating during RF application were aspirated by a vacuum connected to the wand. The target tissue was removed using the wand, and the procedure was terminated (Fig. 2). An unfragmented specimen was obtained (Fig. 3). At the end of the procedure, a clip mark was left in the biopsy region for lesions with previous suspicious pathologic diagnosis. The incision was closed with a single suture (Fig. 4). To prevent burns, the skin was cooled with ice cold water after the procedure in two cases (<2 mm) where the lesion was located very close to the skin. Biopsy specimens and previous CNB results were evaluated by the same single pathologist. Collected data included the histopathologic diagnosis, surgical margin, thermal damage around the specimen, and specimen-fat ratio.

Postprocedural complications were recorded as early complications if they occurred during and immediately after the procedure (up to 60 min) and recorded as late complications (after the departure of the patient from the breast unit) if they occurred in follow-up. After the procedure, patients were followed up by the surgeon at postoperative day 3 for care and incision control; at one and six months, patients were followed up on US by the radiologist. The presence of remaining residual lesions and postop changes were recorded. Further US follow-up was performed in the first and second year according to routine follow-up protocol. The routine mammography was performed at time for scanning (Fig. 5).

Early complications were hemorrhage, skin burn, allergic reaction to local anesthesia, patient fainting during the procedure, and pain during the procedure; late complications were organizing hematomas, large skin burns, and infection at the area of the biopsy. During the procedure, the patients were asked to describe their pain from the treatment and to assign the degree of pain from 1 to 10 according to numeric pain intensity scale.

The specimen thermal damage associated with the RF was classified according to the diameter in 4 categories: Grade 0 (<0.5 mm), Grade 1 (0.5–1.5 mm), Grade 2 (>1.5 mm or thermal damage in diffuse areas), and Grade 3 (diffuse thermal damage or inability to diagnose).

Statistical analysis

In the analysis of the data, PASW Statistics 18 for Windows statistical package program was used. Variables were expressed as mean, standard deviation, frequency and percent. Relations between the variables were tested by Pearson correlation analysis. Chi-square test was used to compare categorical variables. Statistical significance was accepted as $P < 0.05$.

Results

A BLES biopsy was performed on 50 lesions under US or stereotactic guidance. Characteristics of the patients and procedure details are shown in Table 1. The mean age of the patients was 43.16±11.5 years. The lesions were classified as BI-RADS 3 in 26 patients (52%) and BI-RADS 4 in 24 patients (48%). The mean target size was 14.9±4.15 mm. The size of the probe used was 15 mm for 24 patients (48%) and 20 mm for 26 pa-

tients (52%). In one patient, a second probe was used because the lesion was bilobular, extending in different planes. In another case, a second basket was used because the first basket was empty. One symptomatic hematoma developed (2%) but did not require surgical intervention. Two patients (4%) complained of pain during the procedure, and their definition of pain according to numeric pain intensity scale was defined as 4 and 5, respectively. Evaluation of pain showed that the procedure was acceptable, causing minimum pain. In the early period, skin burn, allergic reaction due to local anesthesia, and fainting during the procedure were not seen in any of the patients; also, no large skin burn, no delayed wound healing, and no infection were seen in the late period. All patients had good cosmetic outcomes. On US follow-up, fat necrosis was observed in the lesion area of one patient. In 45 cases, postoperative distortion was observed at one month, and postoperative distortion was observed in 10 patients at six months. In 28 cases (56%), no macroscopic and histopatologic lesions were detected in the surgical area. Radiologic target lesions with a diameter of <10 mm were completely removed histopathologically. In our case series, the mean size of histologically completely removed lesions was 11.3±2.9 mm, while that of lesions with partial resection was 17.9±2.5 mm. The relationship between the number of completely removed lesions and lesion diameter is shown in Table 2.

Prior CNB results were available in all cases except one. Post-CNB and post-BLES pathology results were classified in five groups as fibroadenoma, high-risk lesion, intraductal papilloma, benign lesions, and malignant lesions. Fibroadenoma and complex fibroadenomas were evaluated in the fibroadenoma group, nonproliferative lesions and lesions diagnosed as breast tissue were evaluated in the benign group, and proliferative lesions and atypical proliferative lesions were evaluated in the high-risk group. Since previous CNB was not available in one case, it was not included in the comparative evaluation. In 36 cases (73%), the CNB results and the BLES results were consistent with pathologic diagnosis. The results of 13 cases were discordant (Table 3); five cases classified in the high-risk group after CNB were diagnosed as fibroadenoma after BLES. A case diagnosed as fibroadenoma, a case diagnosed as papilloma, as well as two cases classified in the benign group according

to CNB, were placed in the high-risk group after BLES. After comparative evaluation of histopathologic results between CNB and BLES, upgrade ratio was determined as 10.2% (5/49) and downgrade ratio as 10.2% (5/49), respectively (Table 4).

There was a family history of breast cancer in seven patients and a history of breast carcinoma surgery in one patient. There was only one patient who had a breast-conserving surgery history and had undergone a stereotactic procedure for the fine linear microcalcification area in the surgery area. This case was classified as BI-RADS 4. Pathologic diagnosis after BLES was invasive breast carcinoma. After the procedure, the patient had mastectomy without axillary dissection. There was no residue invasive focus on post-surgical mastectomy specimens. In another malignant case, the lesion showed enlargement in the follow-up by ultrasonography. The diagnosis was benign lobular proliferation, and surgical excision was recommended after CNB. Pathologic diagnosis after BLES was mucinous carcinoma. Invasive tumor cells were not detected when cavitation excision and sentinel lymph node biopsy were performed. The sentinel lymph node biopsy result was negative.

RF-associated thermal damage of specimens was observed in patients as follows: Grade 0, 88%; Grade 1, 10%; and Grade 2, 2%. There was no thermal damage to prevent pathologic diagnosis (Grade 3) in any specimen.

The relationship between fat cell content ratio in the specimen and RF-associated thermal damage diameter was assessed by the Pearson correlation test. We found a significant positive correlation between the diameter of thermal damage and lesion fat cell content (r=0.345, $P = 0.015$).

Discussion

In the solid lesions of a typical sampling of breast lesions, CNBs and VACNBs are frequently the preferred standard methods. Excisional biopsy methods include wire marking, roll marking, excision in the presence of intraoperative US, and the BLES method, which has recently become popular.

BLES is a biopsy technique that uses RF energy to enter a small incision made in the skin under local anesthesia and remove the suspected lesion in a single-piece percutaneously. In addition to its diagnostic use in recent years, BLES is an alternative method that can be used as a therapeutic modality using excision, especially in selected benign cases. It is also a useful method for sampling suspect microcalcifications. A number of case series have shown that this method can be used in lesions detected by US (1, 14). In recent studies, it is emphasized that suspect microcalcification areas that cannot be seen by US should be sampled and excised with mammography guidance (15, 16).

It is possible to demonstrate that the lesion is surrounded in real time when BLES is applied with US guidance and to determine whether the lesion can be completely removed at the macroscopic level. As in our case, it can be predicted that residual lesions may remain in the lobular contoured lesions extending in different planes even though the target lesion dimensions are less than 2 cm. In such cases, a new probe to remove the residual lesion in the same application can be inserted into the same access route, and the procedure can be repeated using the probe at different angles. In order to predict such a condition, it is suggested to measure the lesion dimensions in two separate planes absolutely perpendicular to each other in the US examination prior to the procedure. BLES allows for the removal of lesions less than 20 mm in diameter, unlike other biopsy methods with imaging guidance. This feature has enabled BLES to become an important alternative to surgical biopsy in selected cases (1). Short hospital stays, outpatient setting, minimal incision, and good cosmetic results are the advantages of BLES over surgical biopsies. In surgical (open) biopsies, a wider incision and deep tissue removal are required, especially for deeply located lesions. Furthermore, with BLES, it is not necessary to remove the tract like the surgical biopsies made by marking with wire. This method only allows removal of the target mass, but theoretically reduces the risk of implanting the biopsy tract along the axes during the removal of malignant lesions as it burns the lesion boundaries with RF energy.

The ability to be applied in outpatient clinics without requiring general anesthesia makes BLES a good option, especially for elderly patients. In our case series, we had a 77-year-old patient with gastric carcinoma who had a smooth oval contour breast lesion (17×6 mm) with a significant increase in size compared with the size recorded in the previous examinations of the lesion. The CNB result indicated benign lobular proliferation. However, after BLES, the lesion was diagnosed as mucinous carcinoma. Also, no residual tumor was found in the operation area after surgery.

BLES has several defined complications, all of which can be well tolerated by patients. The complications of the procedure are grouped as early and late complications in the literature (17). In our study, as an early complication, one case (2%) developed hematoma that could be controlled by external compression, and two cases (4%) developed pain during the operation. No late complication developed. Al-Harethee et al. (17) reported early complications in 11 cases (8.2%), including minor hemorrhage controlled by external compression in six cases, hemorrhage requiring deep skin sutures in three cases, and skin burn in two cases. In addition, wound infection in 17 cases (12.6%), delayed wound healing in five cases, minor hematoma in five cases, and antibiotherapy in four cases were reported. Hematoma, infections, and other complications were not reported in a study of 1600 cases by Killebrew et al. (13). In our study, only minor morbidity (1/50; 2%) was

determined; this was compatible with other studies reporting hematoma rates of 0.6% (12) and 16% (18).

Although BLES is a safe and effective method with minor complication rates as reported in many publications in the literature (17), it is a system that cuts and separates tissues with RF energy, leading to thermal damage to the specimen. For this reason, it has been thought that there may be diagnostic failure in pathologic specimens due to thermal damage, and many studies have been done on this subject. In a study by Allen et al. (1), it was reported that most specimens suffered thermal damage in the surrounding tissue less than 0.5 mm from the lesions, which did not cause diagnostic failure (1). In another study of 166 cases by Seror et al. (19), authors reported a 4% rate of thermal damage that leads to pathologic diagnostic failure. In our study, similar to the those in the literature, the thermal damage rates were found in 88% of cases less than 0.5 mm and no specific damage was detected which could lead to diagnostic failure. Additionally, a study by Wasim et al. (20) found that the rate of thermal damage was correlated with the increase in the fat content of the specimen. Similarly, in our study, an increase in the diameter of the burn was observed as the fat content in the specimen increased.

Superiority of the BLES method over VACNB is that the lesion can be removed without being fragmented into small parts, that is, as a single entity, and the surgical margin can be assessed (17). This is important because the inability to accurately sample suspicious lesions histologically will lead to an inadequate histologic diagnosis. For example, in cases with biopsy-resultant ADH, it is possible to detect DCIS after surgery or detect an invasive focus after surgery in a case with biopsy-resultant DCIS. The most important factor that shows the diagnostic reliability of a biopsy method is the low rate of underestimation. In a study of 1600 cases comparing BLES and VACNB methods performed by Killebrew et al. (13) there was a statistically highly significant difference in the underestimation rates in atypical benign lesions, but a much less significant statistical difference in the underestimation rates (3.2%) in DCIS. In the complete excision of DCIS, they found a statistically significant difference between BLES and VACNB. In another study by Sie et al. (12), underestimation rates in atypical lesions were reported as 9.4%, and underestimation rates in DCIS were reported as 5.2%. In our study, atypical lesions were detected in two cases after BLES, but a sufficient number of patients could not be reached for statistical analysis. Because the surgical margin was determined to be negative after BLES, clinical and radiologic follow-up was performed in these two cases.

Our patients did not have surgical biopsy except for two patients in our series who were diagnosed as malignant. No residual tumor was detected in these two patients after surgery. In our study, 28 cases (56%) were detected with complete resection upon radiologic imaging. But in the pathologic evaluation of 11 of these 28 complete removed lesions, surgical border was reported as <1 mm. In the literature, total excision rates were reported as 30%–76.3% (13–24) in malignant lesions; this is similar to the findings in our series. In a systematic review by Sanderink et al. (21) the diagnostic or therapeutic accuracy and safety of BLES was evaluated based on 14 articles and 4272 BLES biopsies. The main lesion size on imaging ranged from 5.7 to 10 mm. Overall complete excision rates ranged from 30%–76.3%. Scaperrotta et al. (15) used BLES for small clusters of suspicious microcalcification in 105 patients and, based on their total excision rates, suggested that BLES may potentially have a therapeutic role in selected patients. However, Milos et al. (16) reported that BLES is a diagnostic tool and cannot be considered as a therapeutic tool because total excision was seen in only 44.1% (15/34) of the lesions. Also, for complete removal target lesion size is important. Medjhoul et al. (14) and Seror et al. (19) compared complete resection rates and target lesion dimensions and reported that target lesions of 10 mm or smaller could be removed with a safe surgical margin. In our case series, 14 out of 28 lesions smaller than 10 mm were completely removed.

In two cases with ADH and atypical lobular hyperplasia (ALH) after BLES, surgical resection was not performed because the surgical margin was negative. In the case of a total excision of the intraductal papilloma diagnosed with a nipple discharge, the nipple discharge discontinued after the procedure. Niinikoski et al. (22) studied feasibility of BLES for the management of small benign and high-risk lesions such as intraductal papilloma and reported 46.6% complete excision rate.

The small number of patients is the major limitation of our study. The inadequacy of our DCIS and ADH numbers to determine underestimation rates is another. However, we have not had enough experience to evaluate the success of BLES in stereotaxic guidance. In order to perform the operation with this method, the probe and probe of the prone table must be compatible with each other. The process has to be supported by manual adjustments, and it is possible to make additional shots in case of incompatibility. In this situation, the experience of the radiologist becomes even more critical. Because of these disadvantages, we could only apply a stereotactic method in one selected case. This was a case of breast-conserving surgery with a diagnosis of breast cancer and a newly developing cluster microcalcification field in the operation region. This case was diagnosed as invasive ductal carcinoma after BLES. The case was accepted as a local recurrence, and mastectomy without axillary dissection was performed.

In conclusion, based on the cases reported in the literature and our own experience in selected cases, BLES is a reliable method with low underestimation rates, especially in ADH and DCIS. As an added advantage, when used in experienced hands, it can provide high diagnostic success and even serve as a therapeutic method in high-risk lesions, such as radial scar, papilloma, and ALH. In the future, we hope that BLES will be able to give promising results in malignant lesions less than 1 cm and lesions with complete response after neoadjuvant chemotherapy. However, it will be necessary to produce a solution for the sentinel lymph node for this method to be practically applied in malignant lesions.
